***Abstract*—The achievement of surface acoustic wave (SAW) devices stable in high-temperature oxidizing atmospheres requires the development of conductive thin film electrodes that can withstand such harsh conditions. Recent studies have demonstrated the suitability of Pt-based alloys, multilayers or nanocomposite films for temperatures up to 800°C. Electrodes based on new materials and structures still have to be developed for applications taking place at higher temperatures. In this perspective, thin films based on iridium could be good candidates regarding the high melting point, and thus the low diffusion coefficients of this noble metal. In particular, Ir-Rh bulk alloys have shown superior performance as spark plug electrodes, which have to resist concurrently to physical and chemical wear such as high-temperature SAW electrodes. Consequently, this paper deals with the high-temperature behavior of Ir-Rh thin films. Ir-Rh alloys and multilayers films, with an Ir atomic ratio between 10 and 50%, are deposited by one-gun**

electron beam evaporation method. The impact on the films of a 4-days annealing treatment at 800°C in air is studied by X-ray diffraction, scanning and transmission electron microscopy, electron energy loss spectroscopy and four-points probe resistivity measurements. It turns out that all the films oxidized during the annealing period. The post-annealing electrical properties are highly dependent of the initial composition of the film: the higher is the Ir rate in the film, the lower is the electrical resistivity after annealing. Moreover, an Rh₂O₃ overlayer, with a thickness of some tens of nanometers, forms at the surface of the film, confirming previous observations made on Ir-Rh bulk alloys. First SAW measurements made on devices based on Ir₃₀Rh₇₀ alloy electrodes are very promising as a SAW signal is still clearly visible after the 4-days annealing process, while no agglomeration phenomenon can be observed.

Index Terms— high-temperature; SAW; Ir-Rh electrodes; multilayers film

I. INTRODUCTION

There is currently a strong industrial request to develop wireless measurement solutions for a variety of industrial applications taking place between 200°C and 1000°C that cannot be addressed by wired sensors. For instance, in metallurgy domain, such sensor could allow an accurate monitoring of the temperature at different positions on a steel band undergoing a thermal annealing treatment cycle, and thus a better adjustment of the annealing line parameters. Surface acoustic wave (SAW) technology could meet this need as SAW devices are passive components, thus requiring neither embedded electronics nor power source to be wirelessly interrogated. These devices are composed of a piezoelectric substrate on which are built interdigitated

conductive electrodes called interdigital transducers (IDTs). The typical thickness of the thin film from which the IDTs are lithographed is one hundred nanometers. One of the main challenges to face in order to achieve high-temperature wireless SAW sensors is the development of the constitutive materials able to withstand elevated temperatures up to 1000°C and corrosive atmospheres, starting with hot air. Concerning the piezoelectric substrate, langasite ($\text{La}_3\text{Ga}_5\text{SiO}_{14}$; LGS) is currently the most appropriate candidate. It has been intensively studied, demonstrating a good stability at high temperature [1, 2]. However, it has to be noted that, under high-temperature vacuum conditions, LGS suffers from surface degradation related to gallium and oxygen losses [3-5]. Regarding the IDTs, the use of a material having good corrosion resistance seems required. First studies naturally turned to platinum regarding its exceptional noble character and a melting temperature as high as 1773°C [6, 7]. However, it was observed that 100 nm-thick Pt thin films agglomerate at temperatures higher than 700°C [8-10]. Agglomeration is a phenomenon specific to thin films, related to their large surface tension, which transforms a continuous thin film in a more stable configuration from the thermodynamics point of view, namely in a collection of separate beads. Agglomeration kinetics depends both on the film thickness and the nature of the film material. The thicker is the film, the slower are agglomeration phenomena. On the other side, as agglomeration is driven by atomic diffusion phenomena, it is slower for metals with higher melting temperature and thus smaller diffusion coefficients. Consequently, agglomeration phenomena can be hindered by adding impurities in pure metal films in order to decrease diffusion coefficients. This strategy was successfully employed by Pereira da Cunha *et al.* who significantly increased the performance of Pt-based IDTs by the use of Pt-Rh alloys, Pt-Rh/ZrO₂ multilayers and Pt-Rh/ZrO₂ nanocomposites. This group successfully operated an LGS-based SAW device with Pt-10%Rh/ZrO₂ nanocomposites electrodes for more than 5 months at 800°C in air atmosphere [11]. Since then, new electrode materials and structures have been investigated

by this group towards establishing stable operation of LGS-based SAW high-temperature sensors at 900°C and beyond [12].

In order to achieve electrodes that are able to operate in corrosive atmospheres at temperatures of 800°C and more, it could be relevant to replace platinum by a noble metal with lower intrinsic diffusion coefficients. In this context, iridium is an appropriate candidate as its melting temperature (2447°C) is significantly higher than that of platinum. First investigations on pure Ir electrodes were very promising, confirming the high resistance of iridium thin films to agglomeration phenomena [10, 13]. However, these results were obtained under vacuum conditions as Ir transforms into volatile IrO₃ above 800°C in oxidizing environments [14]. This drawback could be overcome by alloying iridium with another element. Indeed, Osamura *et al.* studied the high-temperature behavior of spark plug electrodes made of various Ir-based alloys, including Ir-W, Ir-Re, Ir-Mo, Ir-Ru, Ir-Hf, Ir-Pt, Ir-Pd, Ir-Ni and Ir-Rh [15]. Material challenges to face for this application are very similar to those encountered in the development of high-temperature SAW IDTs. Indeed, it is necessary to employ a conductive material with a high melting point to improve the sparking wear resistance. Moreover, as spark plugs are exposed to a hot environment (temperature can exceed 2000°C) containing large amounts of oxygen, it is important that the material from which spark plug electrodes are made be highly resistant to oxidation.

Osamura *et al.* found that among all the investigated Ir-based alloys, Ir-Rh alloys show the best performance in such conditions. In particular, Ir-Rh alloys show a far better resistance to oxidation than pure iridium above 800°C. This phenomenon was explained by the formation of a thin rhodium oxide passivation layer at the surface of the samples during annealing. In fact, Osamura *et al.* assumed that Ir atoms close to the surface transform into IrO₃ and fly off, so that

only Rh atoms remain close to the surface. The latter also oxidize into Rh_2O_3 which is a stable oxide that hinders O diffusion deeper inside the sample. Unfortunately, the thickness of the Rh_2O_3 passivation layer is not given in this study. Note that the Rh protection effect is maximized as soon as the Rh content reaches 10 wt%. Very few other studies were dedicated to Ir-Rh alloys and none of them to Ir-Rh thin films with a thickness in the range of some hundreds nanometers.

Based on Osamura's study, it appears that Ir-Rh thin films could be good candidates for SAW applications taking place in high-temperature oxidizing atmospheres. Consequently, the goal of this study is to make a first investigation on the high-temperature behavior of such Ir-Rh thin films, to determine their relevance for the targeted application.

II. EXPERIMENTAL

Ir-Rh thin films were deposited on Y and Y+50°-cut LGS substrates (Witcore Co. Ltd., Jinan, China) by one-gun electron-beam evaporation method (Edwards Auto 306). The base pressure was $3 \cdot 10^{-8}$ mbar. From $\text{Ir}_{70}\text{Rh}_{30}$ alloy pellets, 150 to 300 nm-thick Ir-Rh alloy thin films were deposited without and over a 10 nm-thick Cr adhesion layer (on Y-cut LGS substrates). From pure Rh and Ir pellets, 120 nm-thick multilayers films (6 to 24 layers) were deposited without adhesion layer (on Y+50°-cut LGS substrates).

SAW delay lines operating at 97 MHz were achieved using photolithography process and ion beam etching, from the Ir-Rh alloy thin films with Cr adhesion layer. The SAW direction was Y-X. The spatial period of the IDTs was 24 μm .

Unprocessed thin films and SAW devices were annealed in air for 4 days at 800°C. After annealing, the samples were cooled down to room temperature. As-deposited and annealed samples were investigated by various methods. The morphology was observed by scanning

electron microscopy (SEM - Zeiss SupraTM 55VP). Phase composition and microstructures were obtained by X-ray diffraction (XRD) in Bragg-Brentano geometry (Bruker D8 advance - $\text{CuK}_{\alpha 1}$; $\lambda = 1.54056 \text{ \AA}$) and transmission electronic microscopy (TEM - JEOL ARM 200F). TEM lamellas were prepared using focused ion beam (FIB) etching. The chemical composition was determined by scanning transmission electron microscopy-electron energy loss spectroscopy (STEM-EELS). The resistivity of as-deposited and annealed films was measured by the four-points probe method. SAW devices were electrically characterized at room temperature, before and after annealing, using a network analyzer (PNA 5230a, Agilent Technologies Inc., Santa Clara, CA) and an RF prober station (S-1160, Signatone Corp., Gilroy, CA).

III. RESULTS AND DISCUSSION

A. Preliminary study: Ir-Rh alloy film deposition

As mentioned in the introduction section, Osamura's study revealed that Ir-Rh bulk alloys resistance to oxidation is maximized from a rhodium weight concentration of 10 % [15]. However, the behavior of Ir-Rh thin films regarding oxidation is unknown. Consequently, in order to secure the Rh protective effect, first evaporations were made from Ir-Rh pellets containing 19 wt.% (30 at.%) of rhodium. Fig. 1 shows the TEM cross-section image of a 300 nm-thick deposited film.

Figure 1: Cross-section bright-field TEM image of an as-deposited 300 nm-thick Ir₁₀Rh₉₀ thin film.

Red points indicate the EELS measurements locations.

EELS measurements were performed at different locations of this film (Tab. I). It appears that the overall composition of the film is far from being Ir₇₀Rh₃₀, but rather Ir₁₀Rh₉₀. The first 100 nanometers (which is the typical IDT thickness) even contain less than 3 at.% of iridium. Based on the physical properties of rhodium and iridium, namely the melting temperatures (1963°C and 2447°C, respectively) and the enthalpies of vaporization (493 kJ·mol⁻¹ and 604 kJ·mol⁻¹, respectively), it can be assumed that this phenomenon comes from the fact that the evaporation rate of rhodium is significantly larger than the one of iridium. Consequently, the Ir rate in the e-beam target and thus in the deposited film progressively increases all along the deposition process, as can be seen in Tab. I. This drawback was advantageously employed in the present study to deposit films with different compositions from the Ir₇₀Rh₃₀ alloy pellets. In the following, results obtained with Ir₁₀Rh₉₀ and Ir₃₀Rh₇₀ alloy films will be shown.

The deposited alloy films showed very poor adhesion properties on bare LGS substrates. As the first deposited layers are nearly Rh layers, this means that rhodium element has not enough affinity for oxygen to form firm bonds with an oxide substrate, such as LGS. Thereafter, a 10nm-thick chromium adhesion layer was successfully employed to enhance the adhesion quality between the Ir-Rh alloys films and the LGS substrates.

Table I: Ir & Rh relative rates in Ir-Rh alloy films as given by EELS measurements.

Measurement locations are shown on Fig. 1

Measurement location number	1	2	3	4
Rh (at.%)	98	96	91	89
Ir (at.%)	2	4	9	11

B. Ir-Rh multilayers film deposition

As described hereinabove, the control of the stoichiometry of Ir-Rh alloy thin films deposited by one-gun electron-beam evaporation is very tricky. Consequently, the rest of the study was dedicated to multilayers films composed by Ir and Rh nanolayers alternately evaporated from pure Ir and Rh pellets respectively. Thereby, the overall film composition depends on the thickness ratio between the successive Ir and Rh nanolayers.

Let us call n the number of moles in one nanolayer, m the mass of the nanolayer, M the molar mass of the element constituting the nanolayer, ρ the density of the nanolayer, S the surface of the substrate and t the thickness of the nanolayer. Thus, n can be expressed as:

$$n = \frac{m}{M} = \frac{\rho t S}{M}$$

Finally, the atomic ratio between rhodium and iridium elements in the multilayers film is:

$$\frac{n_{Rh}}{n_{Ir}} = \frac{\rho_{Rh}}{\rho_{Ir}} \frac{M_{Ir}}{M_{Rh}} \frac{t_{Rh}}{t_{Ir}} = 1.027 \frac{t_{Rh}}{t_{Ir}}$$

Thereafter, the targeted atomic ratio was 1 (in order to obtain Ir₅₀Rh₅₀ multilayers films), so Ir and Rh nanolayers of same thickness were successively deposited. As Sakharov *et al.* reported that Ir thin films adhere well to LGS substrates [16], all multilayers films were successfully deposited starting by an Ir nanolayer. In the same way, the films were ended by an Rh nanolayer in order to take advantage of the Rh₂O₃ passivating layer that could form at the surface. The total thickness of the deposited films was 120 nm. Three kinds of film nanostructure were investigated, depending on the number of nanolayers successively deposited (Tab II). Fig.2 shows the TEM cross-section image of an as-deposited 12x10 nm multilayer film.

Table II: Description of the three investigated nanostructures.

Sample number	1	2	3

C. High-temperature behavior

Fig. 3 shows the XRD patterns of the Ir₁₀Rh₉₀, Ir₃₀Rh₇₀ alloy and Ir₅₀Rh₅₀ multilayers films before and after a 4-days annealing period at 800°C. Based on the calculated Ir-Rh phase diagram available in the literature [17], in which no intermetallic compound can be found, we assume that the alloy films are solid-solution-type. All kinds of as-deposited films crystallized in the face centered cubic (fcc) phase, being textured in the [111] direction.

Ir_xRh_{1-x} (111) XRD peaks are not visible anymore on the XRD patterns of annealed samples. They are substituted by peaks related to several oxides phases. Some peaks can surely be identified as orthorhombic Rh₂O₃ (noted as o-Rh₂O₃ in Fig.3a) in the case of alloy films and as rhombohedral Rh₂O₃ (noted as rh-Rh₂O₃ in Fig.3b) in the case of multilayer films.

Figure 3: As-deposited and post-annealing XRD patterns of Ir₁₀Rh₉₀ alloy film, Ir₃₀Rh₇₀ alloy film (a) and Ir₅₀Rh₅₀ multilayers films (b).

This difference is unexplained. The remaining peaks could be attributed either to IrO_2 or RhO_2 which are both tetragonal form. The theoretical peaks of these two phases are very close and none of them coincides exactly with the experimental reflexes. By adjusting the lattice parameters of IrO_2 (or RhO_2 which comes to the same thing), a good match was obtained. Consequently, we assume that the actual tetragonal phase is $\text{Ir}_x\text{Rh}_{1-x}\text{O}_2$ rather than IrO_2 or RhO_2 . This assumption is strengthened by the fact that the lattice parameters of the hypothetical $\text{Ir}_x\text{Rh}_{1-x}\text{O}_2$ phase were found to follow well the Vegard law.

The resistivity of the as-deposited $\text{Ir}_{10}\text{Rh}_{90}$ and $\text{Ir}_{30}\text{Rh}_{70}$ alloy films is one order of magnitude higher than conventional values for metallic thin films (Tab. III). On the other hand, the electrical resistivity of the as-deposited multilayers films is comprised between $25 \mu\Omega\cdot\text{cm}$ for the $24\times 5\text{nm}$ sample and $40 \mu\Omega\cdot\text{cm}$ for the $6\times 20\text{nm}$ one.

The effect of the annealing process on the electrical properties of the different films is highly dependent of their composition. In the case of the $\text{Ir}_{10}\text{Rh}_{90}$ alloy films, the electrical resistivity gained two orders of magnitude, reaching the value of $21000 \mu\Omega\cdot\text{cm}$. The $\text{Ir}_{30}\text{Rh}_{70}$ alloy films showed a much smaller rise, as the post-annealing resistivity is equal to $400 \mu\Omega\cdot\text{cm}$. Regarding the $\text{Ir}_{50}\text{Rh}_{50}$ multilayers films the final resistivity is lower than $200 \mu\Omega\cdot\text{cm}$, independently from the film nanostructure.

The decrease of the resistivity with the Ir rate can be explained by the large difference in the electrical proprieties between rhodium oxides and IrO_2 . Indeed, Hämäläinen *et al.* reported an electrical resistivity between 5000 and $11000 \mu\Omega\cdot\text{cm}$ for films mixing RhO_2 and Rh_2O_3 grains [18]. On the other hand, IrO_2 shows an exceptionally low resistivity for an oxide. El Kahkani *et al.* found a bulk value equal to $42 \mu\Omega\cdot\text{cm}$ [19], while values between 47 and $300 \mu\Omega\cdot\text{cm}$ were measured for IrO_2 thin films [20, 21]. Consequently, we assume that the conductivity of the $\text{Ir}_x\text{Rh}_{1-x}\text{O}_2$ phase increases with the stoichiometric coefficient x . Moreover, one can observe in

Fig. 3 that the relative intensity of Rh_2O_3 reflexes (compared to the intensity of $\text{Ir}_x\text{Rh}_{1-x}\text{O}_2$ peaks) significantly decreases when Rh atomic content goes from 90% to 70%, and then from 70% to 50%. This phenomenon could indicate that the relative quantity of Rh_2O_3 (compared to the quantity of $\text{Ir}_x\text{Rh}_{1-x}\text{O}_2$) in the post-annealed films decreases when the initial Ir content increases. These two factors, i.e. increase of $\text{Ir}_x\text{Rh}_{1-x}\text{O}_2$ conductivity and decrease of the relative quantity of Rh_2O_3 , could contribute to the increase of the conductivity of the post-annealed films with the initial Ir content.

Table III: Specific electrical resistance (in $\mu\Omega\cdot\text{cm}$) of the different samples before and after annealing.

	$\text{Ir}_{10}\text{Rh}_{90}$ alloy film	$\text{Ir}_{30}\text{Rh}_{70}$ alloy film	$\text{Ir}_{50}\text{Rh}_{50}$ multilayer film (6x20nm)	$\text{Ir}_{50}\text{Rh}_{50}$ multilayer film (12x10nm)	$\text{Ir}_{50}\text{Rh}_{50}$ multilayer film (24x5nm)
As-deposited	125	116	39.6	34.6	25.5
After 100 hours @ 800°C	$2.1 \cdot 10^4$	400	189	188	186

The influence of the annealing process on the nanostructure of the multilayers films was examined by TEM analyses (Fig. 4). It can be observed that the multilayered structure was lost during annealing while a surface layer formed. The latter is completely Ir-depleted as evidenced by the STEM-EELS mapping (Fig. 5). Quantitative EELS measurements reveal the Rh_2O_3 nature of this layer (Tab. IV). In other words, this result fully confirms Osamura's observations on Ir-Rh bulk alloys: an Rh_2O_3 mantle forms at the surface of the films during annealing [15].

The thickness of the Rh_2O_3 surface layer depends on the initial nanostructure of the multilayers films: about 30 nm for the 24x5 nm sample (Fig. 4a) while it is close to 50 nm for the 12x10 nm one (Fig. 4b). The inner part of the film is Rh-depleted, which means that Rh atoms diffuse towards the surface layer during annealing (Tab. IV).

Figure 4: Cross-section bright-field TEM image of 24x5nm (a) and 12x10nm (b) $\text{Ir}_{50}\text{Rh}_{50}$ multilayers films after 100 hours of annealing at 800°C in air.

Red points indicate the EELS measurements locations.

Figure 5: STEM-EELS mapping of the 12x10nm multilayered films after 100 hours of annealing at 800°C in air: Ir (orange), Rh (green) and O (blue).

Table IV: EELS relative chemical composition of the 12x10nm multilayered films after 100 hours of annealing at 800°C.

Measurement locations are shown on Fig. 4b

Measurement location number	1	2	3	4
Rh (at.%)	39.9	20.7	8.0	14.6
Ir (at.%)	0.3	17.2	26.5	23.6
O (at.%)	59.8	62.1	65.5	61.8

First SAW measurements were realized on devices based on 150 nm-thick $\text{Ir}_{10}\text{Rh}_{90}$ alloy films with Cr adhesion layer, before and after a 4-days annealing period at 800°C. As a reminder, the

IDTs are fully oxidized after this annealing process, their resistivity reaching $21000 \mu\Omega\cdot\text{cm}$, as described in the previous section. For that no signal has been registered after annealing. On the contrary, the SAW measurements performed on devices based on 150 nm-thick $\text{Ir}_{30}\text{Rh}_{70}$ alloy films show that a SAW signal is still clearly visible after annealing (Fig. 6). Insertion losses increased by 8 dB during heating, which is certainly related to the threefold increase of the film electrical resistivity (Tab. III). In the same time, the operating frequency shifted towards lower values. The origin of this phenomenon could be mass loading effect, since the mass of the IDTs increased during oxidation process. No agglomeration phenomena can be observed on the IDTs after the 4-days annealing period (Fig. 7). However, some blisters are visible and the finger edges are peeling off. These phenomena could indicate the unsuitability of the Cr adhesion layer for high-temperature applications.

Figure 6: Frequency response (S_{21} magnitude) of a SAW device based on LGS substrate and 150 nm-thick $\text{Ir}_{30}\text{Rh}_{70}$ alloy thin film before and after a 4-days annealing period at 800°C in air.

Figure 7: SEM image of $\text{Ir}_{30}\text{Rh}_{70}$ alloy IDTs after 100h at 800°C in air.

IV. CONCLUSION

Ir-Rh alloy thin films were deposited from alloy pellets on LGS substrates by one-gun electron beam evaporation method. The control of the film stoichiometry was difficult because of the significant difference in the evaporation rates of Ir and Rh elements. Consequently Ir-Rh multilayers films constituted of successive Ir and Rh nanolayers of same thickness were deposited in order to manage the overall film composition. Different nanostructures were achieved by varying the nanolayers thickness.

The high-temperature behavior in corrosive atmosphere of $\text{Ir}_{10}\text{Rh}_{90}$, $\text{Ir}_{30}\text{Rh}_{70}$ alloy films and $\text{Ir}_{50}\text{Rh}_{50}$ multilayers films was investigated by 4-days annealing periods at 800°C in air. XRD analyses revealed the complete oxidation of all samples with the apparition of $\text{Ir}_x\text{Rh}_{1-x}\text{O}_2$ and Rh_2O_3 phases. Electrical resistivity measurements point out that the higher is the initial Ir rate in the film, the lower is the electrical resistivity after annealing. Thus, the resistivity of the $\text{Ir}_{50}\text{Rh}_{50}$ multilayers films was lower than $200 \mu\Omega\cdot\text{cm}$ after the annealing process. TEM analyses show that the multilayer structure was lost during annealing, while an Rh_2O_3 overlayer, with a thickness of

some tens of nanometers, formed at the surface of the film, confirming previous observation made on Ir-Rh bulk alloys. First SAW measurements made on devices based on Ir₁₀Rh₉₀ alloy IDTs showed that the signal was lost. On the other hand, the SAW measurements made on Ir₃₀Rh₇₀ alloy IDTs are very promising as a SAW signal is still clearly visible after the 4-days annealing process, while no agglomeration phenomenon can be observed. Complementary experiments are ongoing to investigate the behavior of SAW devices based on Ir₅₀Rh₅₀ multilayers IDTs.

Various studies will have to be done in order to confirm these first promising results. Longer annealing periods at 800°C will be performed in order to determine the time-evolution of the Rh₂O₃ overlayer observed on the multilayers films after annealing. In the same way, the behavior of the films at higher temperatures, for which pure Ir volatilizes in IrO₃, will be investigated. Finally, Ir-rich multilayers film will be investigated in order to optimize the IDTs electrical behavior.
