L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Stability Analysis and Robustness Assessment of Deterministic and Stochastic Nonlinear Moving Horizon Estimators

Rata Suwantong, Sylvain Bertrand, Didier Dumur and Dominique Beauvois

Abstract—This paper proposes a discussion on the classification of the formulations of nonlinear Moving Horizon Estimators (MHE) of the literature into two categories: deterministic and stochastic. The stability of the dynamics of the estimation error is discussed for the MHEs in both frameworks. This paper also provides full explicit formulation of the stability conditions for the MHE in the deterministic framework, which were not given in the literature. Furthermore, robustness of MHE in both frameworks with respect to model errors is investigated through a simulation example of space object tracking. Comparison with other more classical estimators such as EKF, UKF and particle filter is also achieved.

I. INTRODUCTION

The Moving Horizon Estimator (MHE) computes an estimate at the current instant by solving an optimization problem based on information from a fixed-number of latest measurements collected over a finite horizon. Its optimization parameters are generally the initial state at the beginning of the horizon and the process noise sequence over the horizon. The MHE has been proven to be more robust against model errors, poor initialization and bad tuning compared to classical filters such as the Extended Kalman Filter, the Unscented Kalman Filter and the particle filters [1][2][3].

For discrete time autonomous nonlinear systems with additive process and measurement noises, formulations of the MHE exist in the literature in both deterministic and stochastic frameworks. The deterministic framework refers to the fact that the initial state at the beginning of the horizon, the process noise and the measurement noise are considered to be unknown deterministic variables of unknown characteristics that take their values in known compact sets [4][5][6]. The stochastic framework refers to the case where these parameters are considered as random variables and assumptions on their statistics are made [2][7][8].

A major issue in nonlinear MHE is to provide stability guarantees of the estimation error dynamics. In the stochastic framework, some stability conditions have been provided in the literature [7] but they are difficult to deal with for practical implementation. On the other hand, more tractable conditions have been derived for MHE in the deterministic framework to ensure bounded convergence of the estimation error [5][6].

These stability conditions are based on mild conditions on the continuity of the state equation, the observability of the system and the finite sensitivity to the measurements which are easy to verify in practice. Another condition concerns the weight term on the initial state at the beginning of the horizon which is used in the cost function of the MHE formulation. Explicit formulation of all the terms used in the stability theorem of the MHE in the deterministic framework.

II. PRELIMINARIES

A. Notations

The Euclidean norm of a vector $v$ is denoted by $\|v\|$. For a given matrix $Q$ and vector $v$, we define $\|v\|^2_Q = v^T Q v$. The maximum and minimum eigenvalue of a matrix $Q$ will be respectively denoted by $\lambda^{\text{max}}_Q$ and $\lambda^{\text{min}}_Q$. A function $f(x)$ is said to be locally Lipschitz with respect to its argument $x$ if there exists a positive constant $L_f$ such that $\|f(x') - f(x'')\| \leq L_f \|x' - x''\|$, for all $x'$ and $x''$ in a given region of $x$ and $L_f$ is the associated Lipschitz constant. A continuous function $\phi : [0,a) \rightarrow [0,\infty)$ is said to belong to class K if it is strictly increasing and satisfies $\phi(0) = 0$. A function $\beta(r,s)$ is said to be a class-KL function if, for each fixed $s$, $\beta(r,s)$ is a class-K function with respect to $r$ and, for each fixed $r$, $\beta(r,s)$ is decreasing with respect to $s$ and $\beta(r,s) \rightarrow 0$ as $s \rightarrow \infty$.

B. Model of the System: State and Measurement Equations

The considered autonomous system is modeled by the nonlinear discrete-time equations:

$$
x_{k+1} = f(x_k) + w_k, \quad y_k = h(x_k) + v_k
$$

(1)
where \( x_k \in \mathbb{R}^{n_x} \) is the state vector of dimension \( n_x \), \( y_k \in \mathbb{R}^{n_y} \) is the measurement vector, \( w_k \in \mathbb{R}^{n_w} \) is the process noise, \( v_k \in \mathbb{R}^{n_v} \) is the measurement noise and \( k \in \mathbb{N} \) is the time index.

C. Formulation of the Moving Horizon Estimator (MHE)

Let us consider now the generic formulation of the Moving Horizon Estimator (MHE). Assume that the state vector \( x_k \) has to be estimated at instant \( k \geq N \) using the latest \( N+1 \) measurements collected within the “sliding horizon” \( [k-N,k] \):

\[
y_k = y_{k-N} \quad y_{k-N+1} \quad \cdots \quad y_k^T.
\]

Denote \( \hat{x}_{k-N} \) an a priori estimate of \( x_{k-N} \) and \( \hat{x}_{k-N|k} \) an a posteriori estimate, or shortly an estimate, of \( x_{k-N} \), computed before and after the acquisition of measurement \( y_k \) respectively.

The MHE in both deterministic and stochastic frameworks can be described by the following generic formulation:

\[
\min \ J_k(\hat{x}_{k-N|k}, \{\hat{w}_{k-N+i|k}\}_{i=0}^{N-1}), \quad \forall \{\hat{x}_{k-N+i|k}\}_{i=0}^{N-1} \in \mathbb{R}^{n_x}
\]

subject to:

\[
J_k = \| \hat{x}_{k-N|k} - \hat{x}_{k-N|k-1} \|^2_P + \sum_{i=0}^{N-1} \| \hat{w}_{k-N+i|k} \|^2_Q
\]

\[
+ \sum_{i=0}^{N-1} \| y_{k-N+i|k} - \hat{y}_{k-N+i|k} \|^2_R
\]

where \( \hat{y}_{k-N+i|k} \) is the measurement, \( \hat{x}_{k-N|k} \) is the a priori estimate and \( \hat{x}_{k-N|k} \) is the exact measurement. The a priori estimate \( \hat{x}_{k-N|k} \) at instant \( k \) is computed using the latest \( \{\hat{x}_{k-N+i|k}\}_{i=0}^{N-1} \) obtained by the MHE at the previous instant \( k-1 \). The process noise \( \hat{w}_{k-N+i|k} \) and \( \hat{w}_{k-N+i|k-1} \) are positive definite weight matrices. The estimate of \( x_k \) computed at instant \( k \) by the MHE is denoted by \( \hat{x}_{k|k} \) and is computed using \( \{\hat{x}_{k-N+i|k}, \{\hat{w}_{k-N+i|k}\}_{i=0}^{N-1}\} \) propagated through the state equation (2c). For \( k < N \), the formulation is similar to (2) but with the increasing horizon equal to \( k \) at each instant \( k \) instead.

III. DIFFERENCES BETWEEN MHE IN DETERMINISTIC AND STOCHASTIC FRAMEWORKS

A. Assumptions

As previously stated, the main difference between MHE formulations in both works lies in the representation of uncertainties and the underlying assumptions. In the deterministic framework, the initial state \( x_0 \) at the beginning of the horizon, the process noise \( w_k \) and the measurement noise \( v_k \) are considered as deterministic variables of unknown characteristics taking their values in known compact sets \([5],[6]\). While in the stochastic framework as in \([2],[7],[8]\), these parameters are considered as random variables and assumptions on their statistics are made. These two different main assumptions also impact the way other design parameters are tuned in the MHE algorithm.

B. Parameter tuning

The main parameters of the MHE algorithm are the weight matrices \( P, Q, R \) used in the cost function (2b).

In the stochastic framework, these matrices are usually defined as \( Q = Q^{-1} \) and \( R = R^{-1} \), where \( Q \) and \( R \) are the process noise and the measurement noise covariance matrices respectively.

The matrix \( P \) is defined as the inverse of the a priori error covariance matrix \( P_{k-N|k} \) which should account for information neglected before the horizon of MHE. Therefore \( P_{k-N|k} \) is usually updated using the Extended Kalman Filter equations \([7]\) or sampling-based filters \([8]\).

In the deterministic framework, the work of \([5],[6]\) proposes to define the weight matrix \( P \) as a constant matrix such as \( P = pI_n \), where \( p \in \mathbb{R}^{++} \) and \( I_n \) is the identity matrix of dimension \( n_x \). The choice of the value for this parameter \( p \) is constrained by stability conditions, as it will be discussed in the next section.

C. Stability of the Dynamics of the Estimation Errors

Let us introduce first the definitions concerning the stability of the dynamics of the estimation errors of an estimator.

Definition 1: (Robust Global Asymptotic Stability)

Denote \( \hat{x}_0 \) an a priori initial estimate. The dynamics of the estimation error \( (\hat{x}_k - x_k) \) for the system (1) \( \forall k \in \mathbb{N} \) is Robustly Globally Asymptotically Stable (RGAS) iff \( \forall x_0 \in \mathbb{X} \), \( \forall \hat{x}_0 \in \mathbb{X} \), \( \forall \alpha > 0 \), \( \forall \beta > 0 \), there exist a class-KL function \( \alpha \) and class-K functions \( \beta \) such that \( \forall k \in \mathbb{N} \)

\[
\| x_k - \hat{x}_k \|^2 \leq \alpha(\| \hat{x}_0 - x_0 \|^2, k) + \beta(\| w_0 \|^2, k) + \beta(\| v_0 \|^2, k).
\]

Definition 2: (Observability in \( N + 1 \) steps)

Define the observation map of the system (1) on a window of length \( N+1 \) by

\[
F(x_{k-N}, w_{k-N}) = \begin{bmatrix} h(x_{k-N}) \\ h(f^{w_{k-N}}(x_{k-N})) \\ \vdots \\ h \circ f^{w_{k-N}} \circ \cdots \circ f^{w_{k-N}}(x_{k-N}) \end{bmatrix}
\]

where \( \circ \) denotes function composition and \( f^{\eta}(x) = f(x) + \eta \). Denote also

\[
f^{k_{N+i}}(x_k) = f^{w_{k_{N+i}}(x_{k-N})} \circ \cdots \circ f^{w_{k-N}}(x_{k-N}), \quad i \in \{0, N-1\}
\]

The system (1) is said to be observable in \( N + 1 \) steps if this condition is satisfied: \( \forall (x', x'') \in \mathbb{X}^2 \), there exists a K-function \( \phi(\cdot) \) such that

\[
\phi(\| x' - x'' \|^2) \leq \| F(x', 0_{n_x \times 1}) - F(x'', 0_{n_x \times 1}) \|^2
\]

Let us consider now the work in the literature concerning the stability of the dynamics of the estimation errors for nonlinear MHE in both frameworks.

1) In Stochastic Framework: It is proven in \([7]\) that the dynamics of the estimation errors of the MHE in this framework is RGAS if the system (1) is observable in \( N + 1 \) steps and the term \( \| \hat{x}_{k-N|k} - \hat{x}_{k-N|k} \|^2_P \) which is called an “approximated” arrival cost in \([7]\) is lower than the “exact” arrival cost which is equal to the sum of the cost function concerning every measurement from \( k = 0 \) to \( k - N - 1 \), i.e. \( y_{k-N} \). As stated in \([5]\), this condition is difficult to be used in practice since the exact arrival cost must be computed at each instant which leads to large computational effort. Despite this difficulty to cope with this stability condition in practice, MHE formulation in the stochastic framework has been widely used ans studied in many works \([1],[8],[9],[10]\).
2) In Deterministic Framework: It is shown in [5] that the dynamics of the estimation errors of the MHE in the deterministic framework is RGAS if the weight matrix \( P \) is adequately chosen. An adequate \( P \) can be calculated if the system (1) satisfies the following assumptions:

(A1) \( \mathcal{X} \) is a convex compact set, \( \mathcal{W} \) and \( \mathcal{V} \) are compact sets with \( 0 \in \mathcal{W} \) and \( 0 \in \mathcal{V} \). Define \( r_w = \max_{w \in \mathcal{W}} ||w|| \), \( r_r = \max_{v \in \mathcal{V}} ||v|| \).

(A2) The initial state \( x_0 \) is such that, for any possible sequence of process noises \( \{w_k\} \), the system trajectory \( \{x_k\} \) lies in the convex compact set \( \mathcal{X} \), \( \forall k \).

(A3) \( f \) and \( h \) are \( \mathcal{C}^2 \) functions with respect to \( x \) on \( \mathcal{X} \). \( f \) and \( h \) are therefore also locally Lipschitz of constants \( L_f \) and \( L_h \) respectively.

(A4) The system (1) is observable in \( N + 1 \) steps.

(A5) The system (1) has finite sensitivity, i.e. the minimum of the class-K function \( \phi(\cdot) \) in (5) exists. Denote \( \delta \) the sensitivity parameter of the system (1) defined by

\[
\delta = \inf_{(x',x'')(x',x'') \in \mathcal{X}^2, x' \neq x''} \frac{\phi(||x' - x''||^2)}{||x' - x''||^2} > 0 \tag{6}
\]

Assumption (A5) ensures that a variation of the state vector at the beginning of the horizon \( x_{k-N} \) induces a variation in the observation map \( F(x_{k-N}, w_{k-N}^{k-1}) \) which corresponds to the measurement sequence \( y_{k-N}^{k-1} \) in case of zero measurement noise. The larger \( \delta \) is, the more observable the system is [6] (the smaller the number of the measurements needed for building the estimate).

The theorem on the convergence of the estimation errors of the MHE is proposed in [5] for \( P = pI_n \), with \( p \in \mathbb{R}^+ \) as follows:

**Theorem 1:** For a discrete-time nonlinear system under bounded additive noises as in (1) satisfying assumptions (A1)-(A5), the dynamics of the estimation errors of the MHE designed in the deterministic framework defined in (2) is RGAS if the design parameter \( p \) is chosen such that

\[
c_1 p + \frac{(L_f)^2 c_2 p}{||x'||^2} < 1 \tag{7}
\]

where \( c_1, c_2 \) and \( c_3 \) are suitable positive constants.

This theorem provides a stability condition that is tractable for practical use of MHE in the deterministic framework. However it would require the explicit expression of the constants \( c_1, c_2 \) and \( c_3 \) which were not provided in the literature. These expressions are given here for the case of diagonalizable matrices \( Q \) and \( R \) (see details in appendix A).

\[
c_1 = 6/\lambda_{Q_{min}}^2, \quad c_2 = 12, \quad c_3 = 2\lambda_{R_{min}}^2/3 \tag{8}
\]

IV. Robustness Assessment of MHE Against Model Errors: Case Study

As a case study, we consider a problem of space debris trajectory tracking during atmospheric re-entry on Earth from measurements provided by a radar ground station. For the sake of simplicity, a simplified one dimensional problem is considered as presented in figure 1. In this problem, the acceleration of the debris is governed by gravitational and aerodynamic drag forces. This latter depends on a parameter \( \beta(t) \) (ballistic coefficient) which is unknown and has high variation with respect to time, which makes it difficult to model. This estimation problem is therefore subject to high model errors which can even lead to filter divergence.

![Fig. 1: Space Debris Trajectory in a 1 dimensional case, D: debris and S: radar station (left). Evolutions of the position of the simulated trajectories at each instant in minimum, mean and maximum (right).](image)

A. Simulation of Real Trajectories and Measurements

Monte Carlo simulations of 100 trajectories of the debris during 20 s starting from an altitude close to 70 km have been performed assuming a spherical debris, with a varying \( \beta(t) \), as done in [3]. The minimum, the mean and the maximum of the altitude of the debris at each instant among all the simulated trajectories are shown in figure 1. Radar measurements associated to these trajectories have been computed. In this simplified one dimensional problem, they consist in the distances between the debris and the radar ground station. The evolution of the ballistic coefficient \( \beta(t) \) of the debris is supposed to be unknown to the estimators, which would be the case in reality. This allows to assess the robustness of the estimators with respect to model errors.

The performance of the following estimators will be studied: the Extended Kalman Filter (EKF), the Unscented Kalman Filter (UKF), the Regularized Particle Filter (RPF) and the Moving Horizon Estimators (MHE) in the deterministic framework and in the stochastic framework.

B. Estimation Model

Define as \( x_k = (r_{z_k} \ v_{z_k} \ a_{z_k})^T \) the state at instant \( k \) that has to be estimated. To derive an estimation model for the estimators, let us assume that \( \beta \) is constant over a sampling period \( T_s \). The following state equation is obtained [11]:

\[
x_{k+1} = f(x_k) + w_k = \begin{pmatrix} 1 & T_s/2 \\ 0 & 1 \\ 0 & 0 & 1 \end{pmatrix} x_k + \begin{pmatrix} T_s^2/6 \\ T_s^2/2 \\ T_s \end{pmatrix} f_{z_k} + w_k \tag{9}
\]

where \( f_{z_k} \triangleq \dot{a}_{z_k}(t_k) = (-c_2 v_{z_k} + 2a_{z_k}/v_{z_k})(a_{z_k} + g_E) \), with \( g_E \) the Earth gravity constant, and \( w_k \) is modeled as a discrete-time zero-mean truncated gaussian white noise of covariance...
such that \( R = \langle T \rangle \) chosen which is equal to the period of radar measurements.

The measurement equation is simply \( y_k = r_k + v_k \) where the measurement noise \( v_k \) is modeled as a zero-mean truncated Gaussian white noise of covariance \( R = 10^2 \ m^2 \).

## C. Tuning of the Estimators

For each run, the following parameters are given to each estimator. The sampling period of the estimator \( T_s = 0.1 \ s \) is chosen which is equal to the period of radar measurements. From simulated trajectories, we know that \( \tilde{q}_z \) should be chosen such that \( \sqrt{\tilde{q}_z T_s} = 15 \ m/s^2 \) to capture the variation of \( \tilde{\beta} \) during the sampling period for the first 10 seconds of the trajectories and that \( \tilde{q}_z \) should be chosen such that \( \sqrt{\tilde{q}_z T_s} = 1.5 \ m/s^2 \) to capture the variation of \( \tilde{\beta} \) over a sampling period during the last 10 seconds of the trajectories. To study the robustness of the estimators against bad process noise tuning, \( \tilde{q}_z \) will be considered constant over the whole trajectory and these two values will be tested for the estimators to analyze their performance. Since for the MHEs in both frameworks constraints can be imposed during the optimization, it is supposed that their estimate \( \hat{x} \in \mathbb{X} \) where \( \mathbb{X} \triangleq ([0,100] \ km \times \ [-10000, 10] \ m/s \times \ [-20, 2000] \ m/s^2) \). Concerning the process noise estimate, to have less optimization of parameters, it is supposed that \( \tilde{w}_k = \left( \frac{T_s^2}{2} \ T_s \ 1 \right)^T \tilde{w}_{a/z,k} \) where \( \tilde{w}_{a/z,k} \in [-40,40] \ m/s^2 \) is the only process noise parameter to be estimated at the instant \( k \). The horizon length \( N = 6 \) is chosen. For the MHE in the deterministic framework, \( p = 5 \cdot 10^{-9} \) is chosen, allowing (7) to be verified, and stability to be guaranteed. More details on the calculation of this value for \( p \) can be found in [11], as well as on tuning parameters for the UKF and RPF used as comparison.

## D. Performance Analysis

Let us first define the Root Mean Square Error (RMSE) and the Average Root Mean Square Error (ARMSE) of the \( h \)-th component of the estimate \( \hat{s}_{ik} \)

\[
RMSE(s_{ik}) = \sqrt{\sum_{n_{\text{div}}} \frac{(s_{ik,n} - x_{ik,n})^2}{N_{\text{div}}}}, \quad ARMSE(s_{ik}) = \frac{1}{k_f} \sum_{h=0}^{k_f} \frac{RMSE(s_{ik})}{k_f+1} \tag{10}
\]

where \( M \) is the set of indexes of the non-divergent runs, \( N_{\text{div}} \) the number of its elements and \( k_f \) is the discrete-time index of the final instant \( t_f \). The ARMSE is defined as the RMSE average over all time instants. The RMSE of the position estimate \( \hat{r}_z \) for both process noise cases are presented in figures 2. The ARMSE of \( \hat{r}_z \) are presented in Table I.

## E. Result Analysis

We observe that when the process noise is adequately chosen, the EKF and the UKF provide the smallest estimation errors. However, when the dynamics of the system is not well known, they may provide high errors and therefore should not be used. The RPF is very sensitive to process noise value and did not converge when high model error are considered.

On the other hand, the MHEs are more robust against model errors induced from a bad choice of the process noise parameter. We observe also that the MHE in the stochastic framework provides a peak of errors when the process noise parameter is not well chosen, as for other stochastic estimators. This is not the case for the MHE in the deterministic framework. Even though it provides an overall estimation error higher than the MHE in the stochastic framework, the MHE in the deterministic framework is the only estimator that provides the same level of accuracy for any process noise parameter choice and is therefore the most robust for this tracking problem.

## V. Conclusions and Perspective

In this paper, a discussion has been proposed on the categorization of the formulations of the nonlinear MHE of the literature. Two frameworks have been considered, stochastic and deterministic, depending on the assumptions used to model uncertainties relative to noises and optimization parameters.

The MHE in the stochastic framework proposed to use a weight matrix on the a priori initial state at the beginning of the horizon calculated and propagated using EKF equations. This choice is easy to implement, and has been shown in many works to be efficient for state estimation but conditions to guarantee convergence of the estimates may be difficult to cope with. In the MHE algorithm considered in the deterministic framework, this weight matrix can be more easily defined to satisfy a stability condition. To make it directly usable in practice, explicit formulation of all the terms involved in this condition have been provided in this paper, completing the stability theorem proposed in the literature.

This paper also proposed an assessment of the robustness of these estimators with respect to model errors, through a simulation example, showing the great robustness of both MHEs, and especially the deterministic one.
APPENDIX

We would like to have expressions of the constants \(c_1, c_2\) and \(c_3\) for the convergence of the estimation errors of the MHE defined in (2) when the weight matrix on the arrival cost \(P = pL_n\) and \(Q\) and \(R\) are symmetric positive definite diagonalizable matrices. Following [6], we calculate an upper bound and a lower bound on the optimal cost \(J_k^o\) defined as the cost corresponding to the optimal estimate \(\hat{x}_{k\mid N|k}\), i.e. \(J_k^o \triangleq J(\hat{x}_{k\mid N|k}, \hat{y}_{k\mid N|k}, \hat{y}_{k\mid N})\). Then, combining the upper bound to the lower bound gives the dynamics of the estimation errors and of the estimated process noise sequence.

Using the definition of the observation map in (3), the cost function becomes

\[
J_k = p \left\| \hat{x}_{k\mid N|k} - \hat{x}_{k\mid N|k} \right\|^2 + \sum_{i=0}^{N-1} \left\| \hat{y}_{k\mid N+i|k} \right\|^2_Q
+ \left\| \hat{y}_{k\mid N}^k - F(\hat{x}_{k\mid N|k}, \hat{w}_{k\mid N|k}) \right\|^2_R
\]

Let us define as in [6] \(D_n(x'_{k\mid N}) \in \mathbb{R}\), \(\forall x'_{k\mid N} \in \mathbb{R}^n\), \(\forall w_{k\mid N+i} \in \mathbb{W}, \ i = 0, 1, \ldots, N-1\)

\[
D_n(x'_{k\mid N}) = \begin{pmatrix}
\partial y_{k\mid N} / \partial w_{k\mid N} & \cdots & \partial y_{k\mid N} / \partial w_{k\mid N+1} \\
\vdots & \ddots & \vdots \\
\partial y_{k\mid N} / \partial w_{k\mid N} & \cdots & \partial y_{k\mid N} / \partial w_{k\mid N+1}
\end{pmatrix}
\]

Using (4), we have

\[
D_n(x'_{k\mid N}) = \begin{pmatrix}
0 & \cdots & 0 \\
\partial (h \circ f_{N}^{k\mid N}) / \partial w_{k\mid N} & \cdots & 0 \\
\vdots & \ddots & \vdots \\
\partial (h \circ f_{N}^{k\mid N}) / \partial w_{k\mid N} & \cdots & \partial (h \circ f_{N}^{k\mid N}) / \partial w_{k\mid N+1}
\end{pmatrix}
\]

\[
\Delta_n \triangleq \max_{x'_{k\mid N} \in \mathbb{C}} \left\| D_n(x'_{k\mid N}) \right\| \text{w}_{k\mid N+1} = \text{w}_{n\times N+1}
\]

Define \(\bar{k}\) such that \(\bar{k} \triangleq \max_{i=1, \ldots, N} \tilde{k}_i\) where \(\tilde{k}_i > 0\) are suitable scalars such that \(\tilde{k}_i \| w_{k\mid N+i+1} \|^2 \geq \| h \circ f_{k\mid N+i} \| w_{k\mid N+i+1} \|^2 \| \partial (h \circ f_{k\mid N+i} / \partial w_{k\mid N+i+1}) \| w_{n\times N+1}\)

The constant \(\bar{k}\) exists as we are dealing with compositions of \(q^2\) functions. Although it may not be easily computed, its value only affects the asymptotic bound on the estimation error but not its stability.

Upper Bound on the Optimal Cost \(J_k^o\)

Since \(J_k^o\) is the optimal solution of (2), it is smaller than the cost calculated at the real state \(x_{k\mid N}\) with zero process noise \(\text{w}_{n\times N+1}\). In other words,

\[
J_k^o \leq p \left\| x_{k\mid N} - \hat{x}_{k\mid N|k} \right\|^2 + \left\| y_{k\mid N}^k - F(x_{k\mid N}, \text{w}_{n\times N+1}) \right\|^2_R
\]

\[
\leq p \left\| x_{k\mid N} - \hat{x}_{k\mid N|k} \right\|^2 + \lambda_{\text{max}} \left\| y_{k\mid N}^k - F(x_{k\mid N}, \text{w}_{n\times N+1}) \right\|^2_R
\]

According to [6], the last term on the r.h.s of the above equation follows

\[
\left\| y_{k\mid N}^k - F(x_{k\mid N}, \text{w}_{n\times N+1}) \right\|^2 \leq \lambda_{\text{max}} \frac{N}{2} \frac{(N+1)(2N+1)}{6} \left\| \text{w}_{n\times N+1} \right\|^2_R
\]

where

\[
\lambda_{\text{max}} \triangleq \Delta_n \sqrt{N} \left( \frac{N}{2} \frac{(N+1)(2N+1)}{6} \left\| \text{w}_{n\times N+1} \right\|^2_R
\]

Therefore, we have an upper bound on the optimal cost \(J_k^o\) as follows

\[
J_k^o \leq p \left\| x_{k\mid N} - \hat{x}_{k\mid N|k} \right\|^2 + \lambda_{\text{max}} \frac{N}{2} \frac{(N+1)(2N+1)}{6} \left\| \text{w}_{n\times N+1} \right\|^2_R
\]

Lower Bound on the Optimal Cost \(J_k^o\)

Denote, for \(i = 0, \ldots, N\), \(\hat{x}_{k\mid N}\) any estimate of \(x_{k\mid N}\) and \(\hat{w}_{k\mid N}\) any sequence of estimated process noises from \(k - N\) to \(k - 1\). We would like to compute the cost in (11) for any sequence \((\hat{x}_{k\mid N}, \hat{w}_{k\mid N})\), not necessarily computed at \(k\). Using the triangle inequality proposed in [6], one obtains

\[
\left\| F(x_{k\mid N}, \text{w}_{n\times N+1}) - \hat{F}(x_{k\mid N}, \hat{w}_{k\mid N}) \right\|^2 \leq \lambda_{\text{max}} \frac{N}{2} \frac{(N+1)(2N+1)}{6} \left\| \text{w}_{n\times N+1} \right\|^2_R
\]

Using (5) and (16) and the fact that \(\Delta_n\) is diagonalizable, the third term of the cost function (11) becomes

\[
\left\| y_{k\mid N}^k - F(x_{k\mid N}, \text{w}_{n\times N+1}) \right\|^2_R \leq \Delta_n \sqrt{N} \left( \frac{N}{2} \frac{(N+1)(2N+1)}{6} \left\| \text{w}_{n\times N+1} \right\|^2_R
\]

According to [6], we have

\[
\left\| F(\hat{x}_{k\mid N}, \hat{w}_{k\mid N}) - F(\hat{x}_{k\mid N}, \text{w}_{n\times N+1}) \right\|^2_R \leq \Delta_n \sqrt{N} \left( \frac{N}{2} \frac{(N+1)(2N+1)}{6} \left\| \text{w}_{n\times N+1} \right\|^2_R
\]

Hence, (19) becomes

\[
\left\| y_{k\mid N}^k - F(x_{k\mid N}, \text{w}_{n\times N+1}) \right\|^2_R \leq \Delta_n \sqrt{N} \left( \frac{N}{2} \frac{(N+1)(2N+1)}{6} \left\| \text{w}_{n\times N+1} \right\|^2_R
\]

Using the triangle inequality, we obtain

\[
p \left\| x_{k\mid N} - \hat{x}_{k\mid N\mid k-1} \right\|^2 \geq \frac{1}{2} \left\| x_{k\mid N} - \hat{x}_{k\mid N\mid k-1} \right\|^2 - p \left\| x_{k\mid N} - \hat{x}_{k\mid N\mid k-1} \right\|^2
\]

Again, since \(Q\) is diagonalizable we can write

\[
\sum_{i=0}^{N-1} \left\| \hat{y}_{k\mid N+i} \right\|^2_Q \leq \lambda_{\text{max}} \frac{N-1}{2} \sum_{i=0}^{N-1} \left\| \hat{y}_{k\mid N+i} \right\|^2_Q
\]

Define by \(e_{k\mid N|k} \triangleq x_{k\mid N} - \hat{x}_{k\mid N|k}\) the estimation error associated to the optimal estimate of \(x_{k\mid N}\) given by the MHE computed at instant \(k\) and the associated optimal process
Now, let us combine the upper and the lower bounds on the estimation errors $\hat{w}_{k-N}^{k-1}$ in (23), and using (6), one gets:

$$
\text{Dynamics of the Estimation Errors of the MHE}
$$

where the sequences $\{\hat{\xi}_k\}$ and the associated estimated process noise $\hat{w}_{k-N}^{k-1}$.

Combining the upper bound in (18) to the lower bound in (25) to get

$$
\begin{align*}
\tag{24}
\left(\frac{p}{2} + \frac{\lambda_{\text{min}}}{3} \delta \right) \left\\sup_k \left| e_{k-N}^0 \right|^2 + \lambda_{\text{min}} \left(\text{min}_i \left| \hat{w}_{k-N+\delta i}^0 \right|^2 \right) \leq 2p \left| x_k - \hat{x}_{k-N-1} \right| + e^2
\end{align*}
$$

where $e^2 = \hat{c}_{\text{min}}. N + (\delta_N \sqrt{\delta} r_N^2) \left(\frac{3N(2N+1)}{6} \left(\frac{1}{\lambda_{\text{min}}} \right)^2 \right)$

Now, let us combine the upper and the lower bounds on the optimal cost to have the dynamics of the estimation errors $e_{k-N}^k$ and the associated estimated process noise $\hat{w}_{k-N}^{k-1}$.
