Abstract—This paper presents a novel vehicle motion forecasting method based on multi-head attention. It produces joint forecasts for all vehicles on a road scene as sequences of multi-modal probability density functions of their positions. Its architecture uses multi-head attention to account for complete interactions between all vehicles, and long short-term memory layers for encoding and forecasting. It relies solely on vehicle position tracks, does not need maneuver definitions, and does not represent the scene with a spatial grid. This allows it to be more versatile than similar model while combining many forecasting capabilities, namely joint forecast with interactions, uncertainty estimation, and multi-modality. The resulting prediction likelihood outperforms state-of-the-art models on the same dataset.

I. INTRODUCTION

Automation of driving tasks aims for safety and comfort improvements. For that purpose, Autonomous Driving (AD) systems rely on the anticipation of the traffic scene movements. Consequently, motion forecasting is used in AD algorithms such as path planning and target selection. The main obstacle in this task is the human driver behavior that can neither be modeled nor predicted perfectly. It is especially challenging in negotiating situations with many participants where drivers interactivity plays a determinant role. A technical challenge is to find a representation of the road scene that allows forecasting algorithms to account for interactions within a variable number of observed vehicles. It should do so with an unevenly distributed observation accuracy of a wide partially occluded surrounding area. With the closely related topic of pedestrian motion forecasting, the observation is not embedded in an element of the scene and thus does not suffer from occlusions and uneven accuracy. Two other important aspects are specific to vehicles and should be considered: the importance of the road network structure and of reaction time due to inertia. This requires the understanding of the road network structure and longer time and distance anticipation.

The unknown driver decisions and the perceptions inaccuracies makes forecasting uncertainties unavoidable. In that context, another objective is to control the uncertainties of the motion forecasts. We classify the uncertainties in two

kinds. The first are local maxima of the Probability Density Function (PDF) of future positions called modes. They stand for occurrences of choices, for example, a driver chooses a lane, or the perception system chooses a classification. The second are deviations around each mode that represent the continuous uncertainties. They are small errors made at each step of the process such as perception, estimation, and some model approximations. When considering multiple modes, there is a challenging trade-off to find between anticipating a wide diversity of modes and focusing on realistic ones. To meet the need for anticipation in AD systems, forecasting algorithms must control the two kind of uncertainties and combine that with an interaction aware framework.

II. RELATED WORK

The road scene trajectory forecasting methods have evolved from kinematic models with Kalman filters [1], to hand-made human behavior models such as IDM [2] and MOBIL [3] and currently learned models. They allow longer forecasting horizons (5s) and handle more complex situations with uncertainty assessment and greater accuracy.

Learned models for trajectory and maneuver forecast are compared in the survey [4] with the most widely used models being Hidden Markov Models and Support Vector Machines. Since then, recurrent neural networks mostly using the Long Short-Term Memory [5] (LSTM) architecture have become the standard technology for statistical trajectory forecasting. It has been used with the same kind of hand-crafted interaction features than traditional models such as social force [6] but it failed to generalize to complex situations. This was overcome with the social pooling mechanism in [7]. It places features computed with LSTMs on a coarse *spatial grid* to allow spatially related sequences to share features. The subsequent work [8], used as a baseline in our application, uses convolutional social pooling on a coarse spatial grid.

Spatial grids are representation spaces that are able to account for a variable number of input vehicle without ordering. They are used with an attention mechanism along with Generative Adversarial Networks (GAN) in [9], [10], and [11]. Generative models such as GANs and Variational Auto-Encoders (VAE) are able to describe complex distributions. However, they are only able to generate the output distribution with sampling and do not express the PDF. An extension of the convolutional social pooling made in [12] uses non-local multi-head attention over spatial grids to account for long distance interdependencies. Spatial grid representations limit the field of view to a predefined fixed size and the spatial relation precision to the grid cell size.

*This work was made in collaboration with L2S and Renault SAS

³ École polytechnique, Route de Saclay, 91128 Palaiseau Thomas.Gilles@polytechnique.edu

Moreover, with the exception of occupancy grids, the same features are stored in the grid cells matching empty space than grid cells matching unobserved areas. For pedestrian applications, the limitation of the field of view and unobserved areas are not a problem because the perception system is a camera filming a scene from above that already limits the field of view and that has almost no occluded area. However, this affects vehicle applications that use an embedded perception system. Occupancy grids, as used in [13], solve the occlusion problem but they need fine grids with a lot of cells to keep enough spatial precision. Because of the high number of cells, each one can only store a few features. This only allows simplistic hidden representations of each vehicle and still requires heavy computations. Considering these drawbacks, direct agent to agent attention not relying on spatial grids should be used.

Social attention using a graph representation of vehicles neighbors is produced in [14]. However it only account for local interactions among vehicles within a hand-defined distance threshold. A dot product attention mechanism is produced in [15]. It is inspired from the attention mechanism first developed in [16] for sentence translation. This mechanism allows joint forecast of every vehicle in the observed scenes without spatial limitations. It accounts for long range interactions within a varying number of vehicles and does not require the ordering of the vehicles tracks it takes as input. In [15], this dot product attention is used within a spatio-temporal graph representation of the scene developed in [17]. This representation combines spatial and temporal dependencies that rely on positions, pedestrian relative positions, and time step translations as features. Each are embedded with LSTMs before using the dot product attention for social interactions. This identifies important relations to neighbors to be considered for interactions and combines the pedestrian feature representation with the feature representation of relations. In this work we use the multi-head extension of this attention mechanism, also from [16], with a different road scene representation. We do not rely on spatio-temporal graphs but on a simple temporal embedding followed by social interactions that allows interactions between more complex feature representations than only temporal and relative dynamics. We show in the application section VII that different heads specialize to different and interpretable interaction patterns. Our network outputs a mixture of bivariate Gaussians that is more fit to describe the expected distribution than the simple bivariate Gaussians from [15] and we show that it produces diversified multi-modal forecasts.

Multi-modal forecasts are expressed as predictions with local probability maxima. Mixture Density Networks defined in [18] are used in [8] that predefines driving maneuvers as prediction modes. Each maneuver mode is matched with one Gaussian component of the mixture and a conditional predictor is trained along with a maneuver classifier. As shown in [19], the various modes in the trajectory data are very complex and numerous. Thus, capturing them with a few predefined maneuvers is not enough. Using Gaussian

mixture does not necessarily produce diversified modes. A solution to obtain diverse predicted modes without pre-defining them is proposed in [20]. However, it changes the optimized objective that no longer maximize the forecast likelihood. In [21], another solution that preserves the forecast statistics while producing diversified predictions is proposed. However, both methods rely on VAEs that generate prediction samples but not the PDF. In [22], a Multiple-Trajectory Prediction (MTP) loss is used to produce multi-modal trajectory predictions without the need for sampling. However, as in [20], this modifies the objective function and alters the forecast likelihood.

To the best of our knowledge, our added contributions are:

- The use of multi-head attention for trajectory prediction leading to specialized interactions.
- The Combination of long range attention with joint and multi-modal forecasts.
- Diversified multi-modal predictions while directly maximizing the forecast likelihood leading to a significant improvement of the forecast likelihood.

III. INPUTS OUTPUTS

The inputs are sequences of all vehicle (x, y) positions in a road scene. At each time t_0 , we consider an observation history with a fixed observation frequency and a fixed number of observations n_{hist} . The past trajectory is written $\{(x, y)_k\}_{k=-n_{\text{hist}}+1,0}$. The coordinate system is centered on the ego vehicle position at t_0 .

The outputs are n_{pred} sequences of Gaussians mixtures for each vehicle. It is expressed with a sextuplets $(\hat{x}, \hat{y}, \sigma_x, \sigma_y, \rho, p)$ for each vehicle, at each forecast step and for each mixture component. It defines a Gaussian component $(\mathcal{N}((\hat{x}, \hat{y}), \Sigma), p)$ with

$$\Sigma = \begin{pmatrix} \sigma_x^2 & \rho\sigma_x\sigma_y \\ \rho\sigma_x\sigma_y & \sigma_y^2 \end{pmatrix}$$

the covariance matrix, and p the mixture weight such that for n_{mix} components, $\sum_{m=1}^{n_{\text{mix}}} p_m = 1$.

The forecasting model is a set of functions $\text{pred}_\theta : \text{inputs} \rightarrow \text{outputs}$. The inputs and outputs sets are defined with the cartesian products:

$$\begin{aligned} \text{inputs} & \in (\mathbb{R}^2)^{n_{\text{hist}} \times n_{\text{veh}}} \\ \text{outputs} & \in \left(\left(\underbrace{\mathbb{R}^2}_{\hat{x}, \hat{y}} \times \underbrace{\mathbb{R}_+^2}_{\sigma_x, \sigma_y} \times \underbrace{[-1, 1]}_{\rho} \right)^{n_{\text{mix}}} \times \underbrace{\Delta^{n_{\text{mix}}}}_p \right)^{n_{\text{pred}} \times n_{\text{veh}}} \end{aligned}$$

$\Delta^{n_{\text{mix}}}$ is the n_{mix} elements simplex:

$$\Delta^{n_{\text{mix}}} = \left\{ (p_1, \dots, p_{n_{\text{mix}}}) \in \mathbb{R}^{n_{\text{mix}}} \mid \sum_{m=1}^{n_{\text{mix}}} p_m = 1, p_m \geq 0 \forall m \right\}$$

The pred_θ function set is defined as a neural network with weights θ . pred_θ is equi-variant with permutations along the vehicle axis and it is defined for all numbers of vehicles n_{veh} and forecast steps n_{pred} .

IV. MODEL ARCHITECTURE

This model uses an encoder-decoder structure. It is based on LSTM networks for encoding and forecasting. We propose to add two multi-head self-attention layers to this architecture to account for interactions. The first attention layer is added after encoding to incorporate current time interactions. The second attention layer is added after forecasting time unrolling. This allows the forecast position sequences to remain coherent with each other.

A. Global architecture

Fig. 1: Block representation of our forecasting model. Inputs are the sequence of past observations of each vehicle. Outputs are the Gaussian mixture forecasts.

The figure 1 breaks the model in four parts: Encoder, Self-Attention, Predictor, and Decoder. The two self-attention layers have similar architectures with different weights whereas the encoder, predictor, and decoder are the same for every input.

B. Encoder

The encoder acts as a current state estimation for each vehicle using the past observation sequences. This state is an intermediary vector of the neural network and is difficult to interpret. However, since it should encode the current state with at least the information of position, kinematic state, and interaction features, it should have a sufficient dimension, we chose 128. The input (x, y) position sequences are fed to a one dimensional convolutional layer with a kernel of size 3 sliding over the time dimension that creates sequences of 128 features for each vehicle. This first layer increases the number of features in the vector used for the following computations. A convolution allows this first layer to compute derivatives, smoothed values and other kind of features extracted from positions. Then each feature sequence is encoded with a Long Short-Term Memory (LSTM) [5] into a vector of 128 features for each vehicle.

C. Self-attention

The multi-head self-attention layers allow vehicle interactions while keeping independence from their number and ordering. This mechanism is described in [16] where it is applied on sentence translation. In this section we explain its use for vehicle interactions. The computations made by each attention head is represented on figure 2 and are detailed below.

Each vehicle should pay attention to specific features from a selection of the other vehicles. This is made with four steps: pulling together specific features, identifying these feature collections, enquiring among identifiers, and gathering the results. Each head produces a different selection of features

Fig. 2: Schematic representation of one attention head computations. Blocks L_q , L_v , L_k are matrix multiplications of the input vectors.

using a linear projection of the input tensor resulting in the value tensor V . To identify these features, a key tensor K is associated to each value. Then, each vehicle must select which other vehicle to pay attention to. For that purpose, a query Q is produced to find a selection of keys. The match score between a key and a query is their dot product, it is scaled with the square root of the key dimension $\sqrt{d_k}$ and normalized with a softmax. This produces an attention matrix that contains coefficients close to 1 for matching queries and keys and close to 0 otherwise. The attention matrix is square of size n_{veh} , each coefficient (i, j) is the attention coefficient of vehicle i on vehicle j . Finally, this matrix is used to gather the values from V . Thus, the self-attention computation for each head is written:

$$\text{output} = \underbrace{\text{Softmax}_{\text{dim=last}} \left(\frac{QK^T}{\sqrt{d_k}} \right)}_{\text{attention matrix}} V \quad (1)$$

The outputs from all heads are concatenated and combined with a linear layer. The resulting tensor is then added to the input as in residual networks.

D. Predictor and decoder

Tensors produced with the self-attention layer are repeated n_{pred} times to be fed as time sequences into a second LSTM layer called predictor. This produces intermediary time sequences with some interaction awareness. Within the feature sequences, vehicle interactions may depend on time. Thus, we placed a second multi-head self-attention layer before feeding the output to the decoder.

Feature sequences are decoded with two linear layers shared for each time step and ReLU activations. Finally, a last linear layer produces the mixture of Gaussian coefficients. The output is described in section III. Let o_i be the i^{th} coordinate of the output tensor before the activation function. To constraint it, the following activation function is applied

on each coordinate at every time steps:

$$\begin{aligned} & \{(\hat{x}, \hat{y}, \sigma_x, \sigma_y, \rho, p)\}_{m=1, n_{\text{mix}}} \\ &= \text{activation}(\{o_1, o_2, o_3, o_4, o_5, o_6\}_{m=1, n_{\text{mix}}}) \\ &= \left\{ (o_1, o_2, e^{\frac{o_3}{2}}, e^{\frac{o_4}{2}}, \tanh(o_5), \text{Softmax}(o_6)) \right\}_{m=1, n_{\text{mix}}} \end{aligned}$$

V. ARCHITECTURE DISCUSSION

A. Multi-head self-attention

The general idea of this architecture is to use the good properties of the key-query self-attention layer to account for interactions. This offers flexibility to the model allowing powerful LSTM models to compute the features and predictions with the fixed size inputs it demands while accepting a varying number of interacting vehicles without ordering. This allows the simultaneous forecast of each vehicle in the scene with vehicle to vehicle interactions.

This method could be stated as computationally expensive because attention over n objects relies on computations involving an $n \times n$ attention matrix. However, in our use cases, the number of objects is lower than $n = 30$ and most of the time it remains around 10. This small number makes global attention affordable in all of our test cases.

We show in the application section VII-B that multi-head attention produces interpretable interactions with heads specializing on different interaction patterns.

B. Maneuver free multimodal forecast

With the present model, after defining a constant number of mixture components, they are diversified solely with the loss minimization. The loss is only the NLL value averaged over time. Thus, minimizing it pushes the predicted modes toward those of the data distribution. What is forecast is not a mixture of trajectory density functions but a sequence of position mixture density functions. There is a dependency between forecasts at time t_k and at time t_{k+1} but no explicit link between the modes at those times. To simplify, we assume that mixture components centers define local maxima of the probability distributions and can be tracked in time by matching similar mixture coefficients. They are used as forecast trajectories. Even if the human reasoning and some performance indicators use trajectories, only position probability density at each time steps are needed for the applications such as path planning and safety assessment.

C. Hyperparameters

This model is defined with a few specific hyperparameters that should be tuned: number of encoded features, number of embedding and decoding layers and their activation functions, the number of heads in each self-attention layer, the number of mixture component in the output distribution and the error covariance clipping value. Other choices have been made and should be questioned such as the data normalization (none is used), the use of shortcut connections without layer normalization, the use of LSTM layers and some implicit choices may have been overlooked. Optimizing the hyperparameters with a thorough process could bring some improvements and help understand the model but is

not a part of the present study. In this work, only the general concept was prioritized and the hyperparameters were chosen from experience.

VI. LOSS AND PERFORMANCE INDICATORS

The model is trained with the Adam optimizer [23] that minimizes the negative log-likelihood (NLL) loss. The usual performance indicators for such forecasting models are root mean squared error (RMSE), final displacement error (FDE), and NLL. Only NLL accounts for the multi-modal aspect of the forecast, others are merely computed with the most probable forecast. None of the usual performance indicator is able to judge the a trade-off between forecast accuracy and diversity of the predicted modes. Thus they are not entirely satisfactory and we also consider the Miss Rate (MR).

In the following equations, for the i^{th} sequence at time t_k , we note (x_k^i, y_k^i) the observed positions, $(\hat{x}_k^i, \hat{y}_k^i)$ the most probable forecast positions, and $(\hat{x}_k^{*i}, \hat{y}_k^{*i})$ the forecast position that produces the minimum FDE. N is the number of sequences in the subset of the database on which the computation is made.

The RMSE computation is made with equation (2) with

$$\text{RMSE}(k) = \sqrt{\frac{1}{N} \sum_{i=1}^N (x_k^i - \hat{x}_k^i)^2 + (y_k^i - \hat{y}_k^i)^2} \quad (2)$$

The FDE values are less sensitive to large errors than RMSE. Its computation is made with equations (3).

$$\text{FDE}(k) = \frac{1}{N} \sum_{i=1}^N \sqrt{(x_k^i - \hat{x}_k^i)^2 + (y_k^i - \hat{y}_k^i)^2} \quad (3)$$

The Miss Rate is the rate with which all proposed forecasts miss the final position by more than 2m.

$$\text{MR}(k) = \frac{1}{N} \sum_{i=1}^N \mathbb{1}_{\sqrt{(x_k^i - \hat{x}_k^{*i})^2 + (y_k^i - \hat{y}_k^{*i})^2} < 2} \quad (4)$$

The 2m threshold is not met if maneuvers such as lane changes are missed by all modes. Therefore, it gives an indication on the efficiency of the modes diversification.

The NLL computation, at each forecast time t_k , for each Gaussian component centered on (\hat{x}, \hat{y}) , with the forecast error $\mathbf{d} = (d_x, d_y) = (x - \hat{x}, y - \hat{y})$ and the forecast error covariance defined with $(\sigma_x, \sigma_y, \rho)$ is written:

$$\begin{aligned} \text{NLL}(d_x, d_y, \Sigma) &= \frac{1}{2} \underbrace{\frac{1}{(1 - \rho^2)} \left(\frac{d_x^2}{\sigma_x^2} + \frac{d_y^2}{\sigma_y^2} - 2\rho \frac{d_x d_y}{\sigma_x \sigma_y} \right)}_{\mathbf{d}_k^T \Sigma_k^{-1} \mathbf{d}_k} \\ &+ \ln \left(\frac{2\pi \sigma_x \sigma_y \sqrt{1 - \rho^2}}{\sqrt{|\Sigma_k|}} \right) \end{aligned} \quad (5)$$

The time index k is dropped to improve readability. The computation of the overall NLL value for all mixture components is written:

$$\text{NLL}(d_x, d_y, \Sigma, p) = -\ln \left(\sum_{m=1}^{n_{\text{mix}}} p_m e^{-\text{NLL}(d_{x_m}, d_{y_m}, \Sigma_m)} \right) \quad (6)$$

TABLE I: Comparison of MNLL, RMSE, FDE and MR results with baselines using the same dataset. *CSP(M) results were recomputed with some minor modifications for a fair comparison.

Time horizon		1s	2s	3s	4s	5s
MNLL	CV [25]	0.82	2.32	3.23	3.91	4.46
	CSP(M) [8]*	1.78	3.35	4.24	4.88	5.47
	SAMMP	-0.25	0.95	1.72	2.30	2.78
RMSE	CV [25]	0.76	1.82	3.17	4.80	6.70
	CSP(M) [8]*	0.57	1.25	2.10	3.17	4.49
	GRIP [14]	0.37	0.86	1.45	2.21	3.16
	SAMMP	0.49	1.10	1.83	2.76	3.93
FDE	CV [25]	0.46	1.24	2.27	3.53	4.99
	CSP(M) [8]*	0.37	0.89	1.52	2.32	3.30
	SAMMP	0.31	0.76	1.32	2.00	2.86
MR	CV [25]	0.02	0.20	0.44	0.61	0.71
	CSP(M) [8]*	0.003	0.02	0.11	0.30	0.47
	SAMMP	NA	NA	NA	NA	NA

The mean NLL (MNLL) is the average of the NLL from 6 over the test set. Minimizing the NLL loss maximizes the likelihood of the data for the forecast. However, it tends to overfit part of its output. In [24], NLL overfitting has degraded the results, making the NLL value unreliable as a performance indicator. To avoid it, we clip the standard deviations with a 10cm minimum value.

VII. APPLICATION

This model was implemented using the Pytorch library. The NGSIM datasets US-101 and I-80 and its pre-processing were taken from the published code accompanying the article [8]. This also defines the dataset splitting into training, validation, and test sets. Thus, a fair comparison with these results is made. The dataset contains the tracks of all vehicle position on a road segment observed from a camera. The pre-processing produces data that simulates observations from a given vehicle. Each vehicle is alternatively chosen as the observing vehicle. Its surroundings in adjacent lanes and within a 60m road segment are recorded to produce a local road scene centered on the observing vehicle. This road scene is tracked to produce 8 seconds sequences with all positions being recorded at a 5Hz frequency. The 3 first seconds are used as past observations and the 5 next seconds are used as forecast supervision.

A. Global performance indicators

Table I reports results using the performance indicators defined in section VI. All compared models except for GRIP [14] were trained and computed on the same dataset and evaluated with the same functions. Since CSP(M) only forecasts the observing vehicle trajectory, only the errors for this vehicle are being compared.

Baselines:

Constant velocity (CV): We used a constant velocity Kalman filter with optimized parameters for forecasting on the same data as described in [25].

Convolutional Social Pooling (CSP(M)): We retrained the model from [8]. It uses a maneuver classifier trained with preprocessed data that conditions a predictor for multimodal forecasts. A forecast of the center vehicle trajectory is

made with information from its social environment using the convolutional social pooling mechanism.

Graph-based Interaction-aware Trajectory Prediction (GRIP): We took the published results from [14]. It uses a spatial and temporal graph representation of the scene to make a maximum likelihood trajectory prediction simultaneously for all vehicles in the scene. They obtain the best results in term of RMSE but it does not account for error estimation nor multimodality.

Social Attention Multi-Modal Prediction (SAMMP): The model described in this article.

In [8], the model CSP with unimodal forecast gives better RMSE results than the multi-modal forecast CSP(M). The GRIP model gives the best RMSE results for one trajectory forecasting but other metrics were not produced and it should be extended for multi-modal forecasting. The MNLL value is relative to the whole distribution and is the preferred performance indicator for our goal. We chose six mixture components to match the CSP(M) model and have a fair comparison. A higher number of components usually produce more diversified modes but lower performances on the usual indicators. TODO: update CSP(M) and SAMMP values, comment the comparison.

TODO: update images with ones produced by the 6 mixture components model

B. Attention interpretation

The attention matrices give insights about the importance of some interactions. Some of the head roles can be rationalized by looking at the attention matrix it produces in different contexts. For example, after every tested trainings of the model, one of the heads had specialized for front vehicle attention such as the one in figure 3a. The main attention link always goes from one vehicle to the vehicle in front of it, or to itself if there is no front vehicle.

C. Multi-modal forecasting

On the figure 4, the vehicle 0 aggressively overtakes the vehicle 3. In this situation, the future holds diversified possibilities. The overtake could be aborted or be made less aggressively, also the last observations of acceleration and turning could be the results of perception errors.

The NLL loss training is enough to produce a multimodal output matching those possibilities. Using the unmodified NLL loss prevents biases in the forecast distribution that a different loss function may cause and it indeed leads to much lower NLL values than state-of-the-art results.

VIII. HOW TO EXTEND THIS?

The simplest extension is to add additional observations on each vehicle such as velocity, orientation, size or blinkers. Another simple extension is to match various object classes such as cars, pedestrians and trucks with specific encoders, predictors, and decoders to allow inter-class interactions. These adaptations can easily be made because our forecasting algorithm is model-free.

Our application and the one from [8] both work with NGSIM US-101 and I-80 datasets. They are composed of

Fig. 3: A driving scene top view representation with all observed vehicles and the attention matrix for two heads of the first attention layer. The attention that vehicle i is giving to j is drawn as an arrow from i to j , and a circle when $i = j$ with widths proportional to the attention coefficient and a color varying with the arrow angle. Attention is also visible as color from purple to yellow in the i, j coefficient of the matrices on the left. Past positions are represented in gray.

Fig. 4: Another driving scene top view representation. Superposed forecast probability density functions of the ego position are represented in blue shades in log scale. Ground truth future positions are represented with a green line.

highway straight roads observed from above with a camera. This simplistic configuration do not allow training nor testing of the road network understanding. However, this is an important challenge that our model can be extended to consider.

In the present architecture, self-attention produces keys, queries, and values from the same input to transform the input value. The keys and values can be extended with additional inputs. For example, lane center line discretized as a sequence of position points. A bidirectional LSTM could be a good encoder for this new kind of input. Then, each head of the first attention layer would be extended with two additional linear layers $L_{v_{ext}}$ and $L_{k_{ext}}$, both producing the same number of outputs and each with the same feature dimension as the other linear layers from the attention head. With this new input, extended keys and values would be produced :

$$\begin{aligned} \text{encoded}_{\text{ext}} &= \text{extEncoder}(\text{input}_{\text{ext}}) \\ V_{\text{ext}} &= L_{v_{\text{ext}}}(\text{encoded}_{\text{ext}}) \\ K_{\text{ext}} &= L_{k_{\text{ext}}}(\text{encoded}_{\text{ext}}) \end{aligned} \quad (7)$$

These new keys and values would simply be concatenated to the head usual keys and values:

$$\text{output} = \text{Softmax}_{\text{dim=last}} \left(\frac{Q[K, K_{\text{ext}}]^T}{\sqrt{d_k}} \right) [V, V_{\text{ext}}] \quad (8)$$

The output would match the vehicle features with an additional attention over the new input.

To improve the tracking of trajectories from our output, an infinite number of trajectories may be defined as the optimal transport path between the Gaussian mixture at time t_k and the one at time t_{k+1} . A variable finite number of trajectories would be produced as the optimal transport paths that pass through local maxima.

IX. CONCLUSIONS

We proposed a road scene forecasting solution that produces multimodal probability function forecast simultaneously for each vehicle of the scene. Our method generates interpretable social attention coefficients that will be extended to other road scene observations. Results from our approach have outperformed state-of-the-art results with the NLL indicator. This shows a good forecasting capacity as well as a good uncertainty evaluation leading to a preferred trade-off between accuracy and prediction diversity. Future work will include attention of vehicles to lanes and be based on the recently published Argoverse [26] dataset in urban situations. We expect the urban conditions to cover more complex and highly interactive scenes that are better suited to show the interactive capacity of the proposed solution.
